ABSTRACT

Background
For many years, topical use of fluorides has gained greater popularity than systemic use of fluorides. A possible adverse effect associated with the use of topical fluoride is the development of dental fluorosis due to the ingestion of excessive fluoride by young children with developing teeth.

Objectives
To describe the relationship between the use of topical fluorides in young children and the risk of developing dental fluorosis.

Search methods
Electronic search of the Cochrane Oral Health Group Trials Register, CENTRAL, MEDLINE, EMBASE, BIOSIS, Dissertation Abstracts and LILACS/BBO. Reference lists from relevant articles were searched. Date of the most recent searches: 9th March 09.

Selection criteria
Randomised controlled trials (RCTs), quasi-RCTs, cohort studies, case-control studies and cross-sectional surveys, in which fluoride toothpastes, mouthrinses, gels, foams, paint-on solutions, and varnishes were compared to an alternative fluoride treatment, placebo or no intervention group. Children under the age of 6 years at the time topical fluorides were used.

Data collection and analysis
Data from all included studies were extracted by two review authors. Risk ratios for controlled, prospective studies and odds ratios for case-control studies or cross-sectional surveys were extracted or calculated. Where both adjusted and unadjusted risk ratios or odds ratios were presented, the adjusted value was included in the meta-analysis.

Main results
25 studies were included: 2 RCTs, 1 cohort study, 6 case-control studies and 16 cross-sectional surveys. Only one RCT was judged to be at low risk of bias. The other RCT and all observational studies were judged to be at moderate to high risk of bias. Studies were included in four intervention/exposure comparisons. A statistically significant reduction in fluorosis was found if brushing of a child's teeth with fluoride toothpaste commenced after the age of 12 months odds ratio 0.70 (random-effects; 95% confidence interval
0.57 to 0.88) (data from observational studies). Inconsistent statistically significant associations were found between starting using fluoride toothpaste/toothbrushing before or after the age of 24 months and fluorosis (data from observational studies). From the RCTs, use of higher level of fluoride was associated with an increased risk of fluorosis. No significant association between the frequency of toothbrushing or the amount of fluoride toothpaste used and fluorosis was found.

Authors’ conclusions

There should be a balanced consideration between the benefits of topical fluorides in caries prevention and the risk of the development of fluorosis. Most of the available evidence focuses on mild fluorosis. There is weak unreliable evidence that starting the use of fluoride toothpaste in children under 12 months of age may be associated with an increased risk of fluorosis. The evidence for its use between the age of 12 and 24 months is equivocal. If the risk of fluorosis is of concern, the fluoride level of toothpaste for young children (under 6 years of age) is recommended to be lower than 1000 parts per million (ppm).

More evidence with low risk of bias is needed. Future trials assessing the effectiveness of different types of topical fluorides (including toothpastes, gels, varnishes and mouthrinses) or different concentrations or both should ensure that they include an adequate follow-up period in order to collect data on potential fluorosis. As it is unethical to propose RCTs to assess fluorosis itself, it is acknowledged that further observational studies will be undertaken in this area. However, attention needs to be given to the choice of study design, bearing in mind that prospective, controlled studies will be less susceptible to bias than retrospective and/or uncontrolled studies.

PLAIN LANGUAGE SUMMARY

Is the use of fluoride toothpaste during early childhood associated with discolouration/mottling of teeth?

There is strong evidence that the use of toothpaste containing fluoride can prevent tooth decay (caries) in both children and adults. However, a possible adverse effect associated with the use of fluoride toothpaste is the mottling of permanent teeth due to the swallowing of excessive fluoride by young children with developing teeth. This dental fluorosis can range from, typically, mild white patches on the teeth to severe mottling of the teeth with brown staining. The aim of this review was to evaluate whether the use of fluoride toothpaste by children is associated with an increased risk of developing dental fluorosis in children. The review included 25 studies of different designs; some providing stronger evidence than others. There is some evidence that brushing a child’s teeth with a toothpaste containing fluoride, before the age of 12 months, may be associated with an increased risk of developing fluorosis. There is stronger evidence that higher levels of fluoride (1000 parts per million (ppm) or more) in toothpaste are associated with an increased risk of fluorosis when given to children under 5 to 6 years of age. However, for some children (those considered to be at high risk of tooth decay by their dentist), the benefit to health of preventing decay may outweigh the risk of fluorosis. In such circumstances, careful brushing by parents/adults with toothpastes containing higher levels of fluoride would be beneficial.

BACKGROUND

Use of fluorides has been the most important caries prevention method since the introduction of water fluoridation in the 1940s (Kargul 2003).

For many years, the topical use of fluorides has gained greater popularity than systemic use of fluorides. The term ‘topical fluoride application’ is used here to describe methods that provide fluoride to exposed tooth surfaces at a high concentration for a local protective effect. Fluoride containing toothpastes (dentifrices), mouthrinses, gels and varnishes are the most commonly used topical fluoride agents. These can be used individually or in combination and have been shown to significantly reduce caries in children (Marinho 2002; Marinho 2002b; Marinho 2003; Marinho 2003b; Marinho 2003c; Marinho 2004; Marinho 2004b; Walsh 2010). Unlike the systemic use of fluoride such as fluoride tablets, the topically applied fluorides are not intended for ingestion. Despite this, as the fluorides are put into the mouth, they will eventually be ingested if not removed from the mouth after application. Much of the ingested fluorides will be absorbed by the body and produce systemic effects (Ekstrand 1996).

A possible adverse effect associated with the use of topical fluoride is the development of dental fluorosis due to the ingestion of excessive fluoride by young children with developing teeth. Dental
fluorosis is a hypomineralization of tooth enamel caused by the ingestion of an amount of fluoride that is above the optimal level during enamel formation. Clinically, the appearance of teeth with fluorosis depends on the severity of the condition. In its mildest form, there are faint white lines or streaks visible only to trained examiners under controlled examination conditions. In more involved cases, fluorosis manifests as mottling of the teeth in which noticeable white lines or streaks often have coalesced into larger opaque areas. In the most severe form, brown staining or pitting of the tooth enamel may be present and actual breakdown of the enamel may occur (Pendrys 2000; Rozier 1994).

The exact mechanism through which dental fluorosis develops is not fully understood. There is some evidence in support of the hypothesis that excessive levels of fluoride can interfere with dental enamel formation and cause fluorosis (Chen 2006; Kubota 2005).

The use of topical fluorides in young children is usually associated with inadvertent ingestion and systemic absorption of fluoride. The amount of fluoride ingested depends upon several factors, including the fluoride concentration of the product, quantity used, suction use, etc and may range from approximately 0.1 mg, in the case of dentifrices and mouthrinses, to more than 20 mg, in the case of professionally applied fluoride gels without proper suction (Barnhart 1974; Ekstrand 1987; Lecompte 1987). Although the very mild forms of dental fluorosis do not pose a public health problem, more severe forms will be of aesthetic concern, especially when the upper front teeth are substantially involved. Depending on the magnitude of the alteration in tooth appearance, the severity of fluorosis and the vulnerability of an individual to psychological harm, there can be different degrees of interference with a person’s quality of life. There is a need to get the appropriate balance between the beneficial and harmful effects of topical fluoride therapies (Do 2007).

There have been some earlier traditional narrative reviews on the use of topical fluorides and the risk of developing dental fluorosis (Levy 1994; Pendrys 1990; Stookey 1994). However, a systematic quantitative evaluation of the available evidence has never been undertaken.

**OBJECTIVES**

The primary objective of this systematic review was to describe the relationship between the use of topical fluorides in young children and the risk of developing dental fluorosis.

This review attempted to evaluate the available evidence of different topical fluoride treatment modalities (including gels, toothpastes, varnishes and mouthrinses) used at different concentrations, and at varying duration of use/exposure in increasing the risk of developing dental fluorosis in children with different exposure to systemic fluoride (such as water or salt fluoridation).

**METHODS**

**Criteria for considering studies for this review**

**Types of studies**

Randomised controlled trials (RCTs), quasi-RCTs, cohort studies, case-control studies and cross-sectional surveys in which fluoride toothpastes, mouthrinses, gels, foams, paint-on solutions and varnishes were compared to an alternative fluoride treatment, placebo or no intervention group.

**Types of participants**

Children under the age of 6 years at the time topical fluorides were used.

**Types of interventions**

Topical fluoride therapy (TFT) in the form of toothpastes, mouthrinses, gels, foams, paint-on solutions and varnishes, using any fluoride agent (which may be formulated with any compatible abrasive system, in the case of fluoride toothpastes), at any concentration (ppm F), amount or duration of application, and with any technique or method of application, provided the frequency of application was at least once a year. The comparison group was an alternative fluoride treatment group or placebo (for any method of fluoride application) or no intervention (except for brushing or flossing methods of application) resulting in the following comparison: Any single TFT described above compared with an alternative TFT or placebo or no TFT.

**Types of outcome measures**

The primary outcome measure was the percentage prevalence of fluorosis in the permanent dentition. The timing of the outcome measurement should have been taken when most of permanent teeth of interest were erupted in the study subjects. If available, the prevalence of fluorosis for each tooth type was recorded.

In measuring the percentage prevalence of fluorosis, all children with fluorosis according to the index used were classified as ‘fluorosed’ as opposed to normal. As measured by the common epidemiologic indices for dental fluorosis (Rozier 1994), children with a TSIF (Tooth Surface Index of Fluorosis), TFI (Thylstrup and Fejerskov Index) score greater than zero or Dean's classification of ‘questionable’ or higher were classified as fluorosed.

If the other indices were used, the percentage prevalence of fluorosis as reported by the original investigators using other methods (e.g. photographic method or other index) was to be considered and adopted.
Search methods for identification of studies

With a comprehensive search, we attempted to identify all relevant studies irrespective of language. Papers not in English were considered and translated.

Electronic searches

Relevant studies were identified by searching several electronic databases from date of inception:

- The Cochrane Oral Health Group Trials Register (whole database to 9 March 2009)
- The Cochrane Central Register of Controlled Trials (CENTRAL) (**The Cochrane Library 2009, Issue 1**)
- MEDLINE (1950 to 9 March 2009)
- EMBASE (1980 to 9 March 2009)
- BIOSIS (1969 to 9 March 2009)
- Dissertation Abstracts (1900 to 9 March 2009)

A sensitive search strategy using controlled vocabulary and free text terms was developed for each database (see Appendices).

Searching other resources

Reference lists

All eligible studies retrieved from the searches, meta-analyses and review articles were checked for relevant references. Reference lists of relevant chapters from preventive dentistry textbooks on topically applied fluoride interventions were also reviewed.

Handsearching

Prospective handsearching of five journals (**Community Dentistry and Oral Epidemiology**, **Caries Research**, **Journal of Dental Research**, **British Dental Journal**, **Journal of Public Health Dentistry**) as identified as having the highest yield of eligible clinical studies (at least two) was carried out from January 2007.

Personal contact

Searching for unpublished studies (or 'grey' literature such as technical reports and dissertations, or studies published in languages other than English which may not have been indexed to major databases) by contacting experts in the field of preventive dentistry and oral epidemiology was carried out.

Data collection and analysis

Management of records produced by the searches

Because multiple databases were searched, the downloaded sets of records from each database, starting with MEDLINE, were imported to the bibliographic software package EndNote Library and merged into one core database to remove duplicate records and to facilitate retrieval of relevant articles.

Relevance assessment

All records identified by the searches were printed and checked first on the basis of title, then by abstract (when this was available in English or in languages known by the review authors) and/or keywords by one review author. Records that were obviously irrelevant were discarded and the full text of all remaining records obtained. Records were considered irrelevant according to study design/duration, participants, or interventions/comparisons (if the article was a case report; or the study was not on children younger than 6 years old; or the study did not address one of the topical fluoride therapies (TFTs); or the study did not compare a TFT to an alternative TFT or placebo or no treatment).

Selection of studies for inclusion

An inclusion criteria form was prepared and pilot tested, one review author assessed all studies for inclusion in the review, and a second review author independently duplicated the process. A third review author was consulted to achieve consensus.

Data extraction and management

Data from all included studies were extracted by two review authors independently using a pilot tested data extraction form. Again, any disagreements were discussed and a third review author consulted to achieve consensus where necessary. If data were presented only in graphs and figures, we intended to extract it where possible, however, this did not occur in any of the included studies. Data were extracted from tables and text for all included studies. Attempts were made to contact authors in order to obtain missing information or for clarification whenever necessary. Papers not in English had the data extracted with help from appropriate translation.

Descriptive data that were extracted from each study in addition to those described for participants, interventions, outcome measures and methodological quality include: exposure to other fluorides, mode and setting of use, year study started, country/place of study, duration of study, age at which topical fluoride was used, dose of fluoride, duration of use, level of caries reduction. In addition, outcomes may have been assessed at more than one period of follow-up. We intended to make decisions on which
outcome assessment timing to use however once again this did not occur in the included studies.

Assessment of risk of bias

An assessment of the risk of bias in included studies was undertaken following the recommendations as described in Chapter 8 of the Cochrane Handbook for Systematic Reviews of Interventions 5.0.1 (Higgins 2008).

A specific tool for assessing risk of bias in each included study was adopted. This comprised a description and a judgement for each entry in a risk of bias table, where each entry addressed a specific feature of the study:

- Adequate sequence generation
- Allocation concealment
- Blinding
- Incomplete outcome data addressed
- Free of selective reporting
- Free of other bias.

The judgement for each entry involved answering a question, with answers ‘Yes’ indicating low risk of bias, ‘No’ indicating high risk of bias, and ‘Unclear’ indicating either lack of information or uncertainty over the potential for bias. An assessment of the overall risk of bias was summarized involving the consideration of the relative importance of different domains.

It is reminded that the above tool was not developed with non-randomised studies (NRS) in mind, and the six domains are not necessarily appropriate for NRS. However, the general structure of the tool and the assessments were useful to follow when creating risk of bias assessments for NRS. For non-randomised interventional studies, the methods that The Cochrane Collaboration recommends for randomised trials were applied. For cohort and case-control studies, the Newcastle-Ottawa Scale was used (Wells 2008).

We developed our own criteria for the assessment of risk of bias of the cross-sectional surveys with retrospective assessment of exposure:

- Sampling procedure
- Diagnosis of fluorosis
- Ascertainment of exposure
- Non-response rate (considered response rate >65% as adequate).

Assessment of quality of outcome measures was based on the training, calibration and experience of examiners.

Due to the diversity of study designs, a team of at least three experienced review authors discussed the methods of the individual included studies in detail until consensus was reached regarding the risk of bias.

Where uncertainty could not be resolved, efforts were made to contact authors directly for clarification.

Data analyses

Main outcome

The chosen measure of treatment effect was risk ratio for controlled studies or prospective studies, while for the case-control studies or cross-sectional surveys, odds ratio was chosen as the measure of treatment effect. Where both adjusted and unadjusted risk ratios or odds ratios were presented for case-control and cross-over studies the adjusted value was included in the meta-analysis.

Since the data from non-randomised studies are more prone to bias and are often heterogeneous (Loke 2007), separate meta-analyses were carried out and results presented according to different study designs.

The Cochrane Review Manager software (RevMan) was used for estimation of overall treatment effects/meta-analysis of results whenever possible. Random-effects (RE) models were used to calculate a weighted average of the treatment effects across the studies under review, after adjusting for the effects of the confounding factors such as exposure to systemic fluoride. If there were fewer than four studies, fixed-effect (FE) analysis was used, as the estimate of between-study variance is poor for analyses with low numbers of studies.

Investigation of heterogeneity

Heterogeneity in the results of the studies was assessed by inspection of a graphical display of results and by formal tests of homogeneity using $I^2$; the significance of any heterogeneity was reported. Potential sources of heterogeneity were to be investigated where appropriate, and ‘post hoc’ analyses reported as such, with findings treated with caution.

RESULTS

Description of studies

See: Characteristics of included studies; Characteristics of excluded studies.

Results of the search

There were 3573 de-duplicated papers identified from the electronic databases (from the date of inception until March 2009) using the search strategy. All records were screened on the basis of title, keywords and abstracts, 3497 papers that were obviously irrelevant were discarded. Then 76 papers were considered potentially eligible and full text reports were retrieved for further assessment. From these, 14 review articles/guidelines were identified and references were examined for additional relevant studies (Alvarez 2009;
Clark 1993; Cunha 2006; Gillcrist 1996; Holloway 1997; Ismail 2008; Manji 1986; Mascarenhas 2000; Ripa 1991; Steiner 2004; Stookey 1994; Tobin 1988; Warren 1999; Whelton 2004). Thirteen studies were identified, however, all these had been included in the original search, thus no additional studies were included.

Excluded studies
From the remaining 55 studies (62 papers), 29 studies (29 papers) were excluded (see Characteristics of excluded studies for the description of reasons of exclusion for each study). Five studies were conference proceedings/abstracts which did not provide sufficient information. Eleven studies had no or unclear investigation of topical fluoride exposure before the age of 6 years. Five studies investigated the combined exposures of systemic and/or topical fluoride. Four studies used the DDE index or evaluation of enamel defects as the outcome measure. One study had no clinical assessment of fluorosis. Two studies reported were unobtainable. One study’s database no longer existed, thus data from 5 years old could not be extracted.

One study (Larsen 1987) is still pending for eligibility for this review awaiting translation.

Included studies
A total of 25 studies (32 papers) were included in this review with one non-English report (see Characteristics of included studies for details of each study). All the reports were published between 1988 and 2006. There were two randomised controlled trials (RCTs) (Holt 1994; Tavener 2006), one cohort study (Franzman 2006), six case-control studies (Osuji 1988; Pendrys 1989; Pendrys 1994; Pendrys 1996; Pendrys 1998; Skotowski 1995), and 16 cross-sectional surveys (Beltran-Valladares 2005; Bottenberg 2004; Brothwell 1999; Conway 2005; Do 2007; Mascarenhas 1998; Maupome 2003; Morgan 1998; Pereira 2000; Riordan 1993; Riordan 2002; Rock 1997; Saggeri 2007; Szpunar 1988; Tabari 2000; Wang 1997). Of these, 12 had data available to be extracted for analyses; 13 studies had only limited data available that were not in a useable form or missing data. Results of these 13 studies are summarized in Additional Table 1. Of the 25 included studies, nine (36%) were conducted in Europe (UK, Belgium, Norway, Sweden); eight (32%) in the USA; three (12%) in Canada; two (8%) in Australia; one in Brazil (4%); one in Mexico (4%) and one in India (4%). Twelve studies (48%) were conducted in non-fluoridated areas (Bottenberg 2004; Brothwell 1999; Conway 2005; Franzman 2006; Holt 1994; Mascarenhas 1998; Pendrys 1989; Pendrys 1996; Pereira 2000; Skotowski 1995; Tavener 2006; Wang 1997); eight (32%) in fluoridated areas (Beltran-Valladares 2005; Maupome 2003; Morgan 1998; Osuji 1988; Pendrys 1994; Pendrys 1998; Riordan 1993; Rock 1997) and five in both non-fluoridated and fluoridated areas (20%) (Do 2007; Riordan 2002; Saggeri 2007; Szpunar 1988; Tabari 2000).

The age range of the children at the time of the assessment of fluorosis was 6 to 17 years.

Characteristics of interventions/exposure
From the two RCTs, toothpastes at different fluoride levels were compared. In one trial (440 ppm versus 1450 ppm fluoride toothpaste), children entered the trial when they were approximately 12 months old until they were 5 to 6 years old (Holt 1994). They were then followed up for the assessment of fluorosis in school when they were 8 to 10 years old. Children in the other trial (550 ppm versus 1000 ppm fluoride toothpaste) entered the trial at the age of 2 years until they were 5 years old (Tavener 2006). They were followed up for the fluorosis assessment when they were 9 years old. For the cohort study, a birth cohort from eight hospitals was followed up, with fluorosis examined at 7 to 11 years of age. Data on toothbrushing patterns and use of fluoride toothpaste were collected through questionnaires sent to mothers at 6 weeks, 3 months and then at 3 to 6 monthly intervals (Franzman 2006). For the case-control studies and cross-sectional surveys, topical fluoride (TF) exposures of the children before the age of 6 years were mostly investigated using parental retrospective self-administered questionnaires. Variables concerning these exposures included: age started toothbrushing, age started using fluoride toothpaste, frequency of toothbrushing, amount of fluoride toothpaste used, and fluoride level of toothpaste used.

Data from all the included studies, with data available for analysis, were categorised into the following comparisons according to the TF exposures:

- Comparison 1: Age started using fluoride toothpaste/toothbrushing: case-control study (Osuji 1988; Skotowski 1995)
- Comparison 4: Amount of fluoride toothpaste used: cross-sectional survey (Conway 2005; Do 2007; Tabari 2000)
- Comparison 5: Fluoride level of toothpaste used: RCT (Holt 1994; Tavener 2006)

Characteristics of outcome measures
In measuring the percentage prevalence of fluorosis, 14 studies used the Thylstrup and Fejerskov Index (TFI) score (Bottenberg 2004; Conway 2005; Do 2007; Holt 1994; Mascarenhas 1998; Maupome 2003; Osuji 1988; Pereira 2000; Riordan 1993;
Riordan 2002; Rock 1997; Tabari 2000; Tavener 2006; Wang 1997), five studies used the Fluorosis Risk Index (FRI) (Franzman 2006; Pendrys 1989; Pendrys 1994; Pendrys 1996; Pendrys 1998), three studies used the Tooth Surface Index of Fluorosis (TSIF) score (Brothwell 1999; Skotowski 1995; Szpunar 1988) and three studies used Dean's Index (Beltran-Valladares 2005; Morgan 1998; Sagheri 2007). The percentage prevalence of fluorosis ranged from 10% to 72% (see Additional Table 2 for the reported prevalence of each study).

Risk of bias in included studies

Risk of bias is reported separately for randomised controlled trials (RCTs), cohort study, case-control studies and cross-sectional surveys and presented in Additional Tables 3 to 6. Greater weighting is given to intervention studies over observational studies (and prospective, controlled observational studies over retrospective studies) in the interpretation of the findings. For the two RCTs, one trial had adequate sequence generation (Tavener 2006) and the other was not clear (Holt 1994). Both trials had provided information on allocation concealment, had addressed the issue of incomplete outcome data and were free of selective reporting. One trial had been able to blind the outcome assessor but not the participants (Tavener 2006) while the other had been able to blind the participants and was not clear regarding the blinding of the outcome assessor (Holt 1994). One RCT was considered at low risk of bias (Tavener 2006). The results of the assessment of risk of bias for the RCTs is presented in Table 3. Given the inherent biases associated with observational studies, none were judged to be at low risk of bias. The assessment of each included study, grouped by design, is presented in Table 4; Table 5 and Table 6. Only one study met all the assessment criteria for its study design (case-control) (Osuji 1988).

Effects of interventions

Data extracted from the study reports are given in Additional Table 7 which includes both adjusted and unadjusted values if both were presented. The data presented in the forest plots and meta-analyses are adjusted risk ratios (RRs) and odds ratios (ORs), when both were presented in the same paper.

Comparison 1: Age started using fluoride toothpaste/toothbrushing: case-control study (Figure 1).

Data from two case-control studies were included in this meta-analysis, with both providing data on whether the child brushed/had their teeth brushed with fluoride toothpaste before or after 24 months (Osuji 1988; Skotowski 1995). One study showed a statistically significant reduction in fluorosis in starting brushing after 24 months (Osuji 1988) and the meta-analysis also found a significant reduction in fluorosis (OR 0.29, fixed-effect (FE) 95% confidence interval (CI) 0.15 to 0.53). There was an indication of significant heterogeneity between the two studies (P = 0.002, $I^2 = 90\%$). It is not possible to investigate heterogeneity with only two studies, however, one study was conducted in a fluoridated (Osuji 1988) and the other in a non-fluoridated (Skotowski 1995) area. One study (Osuji 1988) was assessed as at low risk of bias, with Skotowski 1995 assessed as moderate as the cases were not felt to be representative.

Figure 1. Forest plot of comparison: 1 Age started using fluoride toothpaste/toothbrushing: case-control study, outcome: 1.1 Fluorosis.
Comparison 2: Age started using fluoride toothpaste/toothbrushing: cross-sectional survey
(Figure 2).
Nine cross-sectional surveys were included in this meta-analysis. Seven additional cross-sectional surveys collected data on age at commencement of toothbrushing, however, no useful data were available for inclusion in the meta-analysis (Table 1).

Figure 2. Forest plot of comparison: 2 Age started using fluoride toothpaste/toothbrushing: cross-sectional survey, outcome: 2.1 Fluorosis.

Three studies provided data on brushing with fluoride toothpaste before or after 12 months (Brothwell 1999; Conway 2005; Tabari 2000) (with one study providing data in two areas); one study provided data on brushing with fluoride toothpaste before or after 14 months (Wang 1997); and five studies provided data on brushing before or after 24 months (Beltran-Valladares 2005; Bottenberg 2004; Do 2007; Mascarenhas 1998; Sagheri 2007), with one study providing data in two areas (Sagheri 2007).

Brushing before 12/14 months

The data for the four studies brushing before 12 and 14 months were combined in the meta-analysis and showed a significant reduction in risk of fluorosis if children brushed their teeth/had their teeth brushed after 12 to 14 months (OR 0.70, random-effects (RE) 95% CI 0.57 to 0.88), with no evidence of heterogeneity (P = 0.22, I² = 30%). None of the four studies were considered to be at low risk of bias and all were conducted in non-fluoridated areas, other than one with both fluoridated and non-fluoridated areas included in the study by Tabari 2000.

Brushing before 24 months

The meta-analysis result for brushing before versus after 24 months was not significant (OR 0.92, RE 95% CI 0.71 to 1.18). None of the five studies were considered to be at low risk of bias, with one being conducted in a fluoridated area (Beltran-Valladares 2005), two in non-fluoridated areas (Bottenberg 2004; Mascarenhas

Topical fluoride as a cause of dental fluorosis in children (Review)
Copyright © 2010 The Cochrane Collaboration. Published by John Wiley & Sons, Ltd.
1998) and two in both fluoridated and non-fluoridated areas (Do 2007; Sagheri 2007).

Comparison 3: Frequency of toothbrushing: cross-sectional survey

(Figure 3).
Four cross-sectional studies provided data for the forest plots (Beltran-Valladares 2005; Conway 2005; Do 2007; Tabari 2000). Four additional cross-sectional surveys collected data on frequency of toothbrushing, however, no useful data were available for inclusion in the meta-analysis (Table 1).

Comparison 4: Amount of fluoride toothpaste used: cross-sectional survey

(Figure 4).
Three cross-sectional studies presented data on the association between the amount of fluoride toothpaste and fluorosis for the forest plots (Conway 2005; Do 2007; Tabari 2000). Three additional cross-sectional surveys collected data on amount of fluoride toothpaste, however, no useful data were available for inclusion in the meta-analysis (Table 1).
Available data were presented as a small versus medium to large amount of fluoride toothpaste on the toothbrush (Do 2007) and pea size versus greater than pea size (Conway 2005; Tabari 2000). One study also presented <0.25 grams versus >0.25 grams (Tabari 2000; data shown in Table 7). The small amount and pea size estimates were combined in the meta-analysis which found no significant effect (OR 0.92, RE 95% CI 0.67 to 1.28). None of the studies were assessed as at low risk of bias. One study was conducted in a non-fluoridated community (Conway 2005), and the other two in both fluoridated and non-fluoridated communities (Do 2007; Tabari 2000).

Comparison 5: Fluoride level of toothpaste used: RCT
(Figure 5).
Two randomised controlled trials compared the effect of giving children different levels of fluoride toothpaste. One study compared 550 with 1000 ppm fluoride (Holt 1994) and the other compared 440 with 1450 ppm fluoride (Tavener 2006). Both studies found statistically significant differences (RR 0.75, 95% CI 0.57 to 0.99) and (RR 0.59, 95% CI 0.44 to 0.79), indicating a higher level of fluoride toothpaste was associated with an increased risk of fluorosis. One study was assessed as at low risk of bias (Tavener 2006) and both studies were in non-fluoridated areas.

Among these three studies, two gave information about the levels of fluoride in the toothpastes being used by the children (250-500 versus >1000 ppm fluoride; Conway 2005) and (400-550 versus 1000 ppm fluoride; Do 2007). The other study classified this as ‘children’ versus ‘family’ fluoride toothpaste (Tabari 2000). The meta-analysis found no statistically significant difference. Neither of the studies were assessed as at low risk of bias. One study was conducted in a non-fluoridated community (Conway 2005), the others in both fluoridated and non-fluoridated communities (Do 2007; Tabari 2000).

Discussion

The objective of this review was to evaluate the available evidence in increasing the risk of developing dental fluorosis in children of different topical fluoride treatment modalities (including gels, toothpastes, varnishes and mouthrinses) used at different concentrations, and with varying duration of use/exposure. The Developmental Defects of Enamel (DDE) Index was not included as an outcome measure within the current review. The DDE Index is not fluorosis specific and, as such, it may not be appropriate to extract information on the prevalence and severity of fluorosis in studies on children using the DDE Index alone. Three papers which had used the DDE Index were excluded from this review. In two of these papers (Ellwood 1994; Evans 1991), the authors specifically referred to their observations as enamel opacities or diffuse enamel defects. In the other one (van der Hoek 2003), the authors mentioned that the prevalence of diffuse opacities was only an approximation to the prevalence of fluorosis. Studies using the Fluorosis Risk Index (FRI) were included, however, the way the results were presented made it difficult to extract the relevant data and pool them with those from other studies which used other indices of fluorosis measurement based on examination of all teeth and all surfaces. Thus results from these studies are reported in Additional Table 1.

The review used a binary approach to the presence/absence of fluorosis. The inclusion of a level of fluorosis that is of aesthetic concern is subject to debate as there is no consensus on this. This was included in the original protocol but removed following peer review. It is acknowledged that the available evidence in the review focuses on mild fluorosis.
Among the 25 included studies, many evaluated the age toothbrushing/use of fluoride toothpaste started, frequency of toothbrushing, amount of fluoride toothpaste used and fluoride level of toothpaste used before the age of 6 years. In two studies (Bottenberg 2004; Skotowski 1995), data on the above mentioned topical fluoride exposures were not included in the meta-analysis because they referred to the exposure at the time of the investigation of fluorosis (i.e. older than 6 years). Also for Mascarenhas 1998, no clear categorization of the frequency of toothbrushing and amount of fluoride toothpaste used was reported, thus these data were also not included in the meta-analysis. In the original protocol, it was intended to include different topical fluoride therapies in the form of toothpastes, mouthrinses, gels, foams, paint-on solutions, and varnishes. However, after conducting the review, evidence generally focused on fluoride toothpaste. A few studies evaluated the use of mouthrinses (Brothwell 1999; Osuji 1988; Szpunar 1988) or professional application of fluoride (Brothwell 1999; Morgan 1998; Osuji 1988), however, these evaluations did not clearly specify the ages at which the children were exposed to the topical fluorides and were not included in the meta-analysis. Thus, the meta-analyses performed in this review mainly focused on the associations between age started using fluoride toothpaste/toothbrushing, frequency of toothbrushing, amount of fluoride toothpaste used, and of fluoride level of toothpaste used and fluorosis. If information on the use of other topical fluoride therapies in causing fluorosis is available in future publications, it will be included in the update of the review.

Regarding the age of fluoride toothpaste/toothbrushing started, a significant reduction in the risk of fluorosis was found if children did not brush their teeth/have their teeth brushed with fluoride toothpaste until after the age of 12 months. However, inconsistent associations were found regarding children beginning to brush their teeth/have their teeth brushed with fluoride toothpaste after the age of 24 months and fluorosis. Data from the case-control studies showed significant reductions when not starting until after 24 months but data from cross-sectional surveys did not. It is noted that the results of the two case-control studies were very different, one had a very small and significant odds ratio (OR) indicating significant reduction in the risk of fluorosis if toothbrushing started after 24 months (Osuji 1988) and the other study (Skotowski 1995) had an insignificant OR laying within the range of ORs from the cross-sectional surveys. When pooling the data from these two studies, an overall significant result was obtained. One should be cautious in interpreting such results and more evidence with low risk of bias is needed to clarify the inconsistency in the association.

No significant association was found between frequency of toothbrushing and fluorosis. Also no significant association was found between the amount of fluoride toothpaste used and fluorosis. It should be noted that the measurements used in determining the amount of fluoride toothpaste used in the included studies were actually vague and subjective: small versus medium to large amount of fluoride toothpaste on the toothbrush, or pea size versus greater than pea size. The frequency of toothbrushing and the amount of fluoride toothpaste used were actually proxy measurements for the amount of fluoride toothpaste being ingested, as part of the ingested fluoride will be absorbed by the body and produce the systemic effects which lead to development of fluorosis in the developing permanent teeth during early childhood (Ekstrand 1996). However, to measure the amount of fluoride toothpaste being ingested has been a very difficult task. Among the included studies, a few studies (Do 2007; Mascarenhas 1998; Riordan 1993; Wang 1997) had collected information on whether the children liked, swallowed or ate fluoride toothpaste as another proxy measure for the amount of ingestion. All these additional measures are considered to be subjective, and thus data from these investigations were not included in the present review.

Regarding the fluoride level of the toothpaste used, results from the two randomised controlled trials (RCTs) found that using toothpaste with a higher level of fluoride was significantly associated with an increase in fluorosis. The study in which children were recruited at 12 months and the fluoride toothpaste intervention was given until the age of 5 to 6 years (Tavener 2006) demonstrated a higher risk of developing fluorosis compared to the other study in which children were recruited at age 2 years and the fluoride toothpaste intervention programme was given for a 3-year period (Holt 1994). However, it is noted that the levels of fluoride used in the former study was 440 versus 1450 ppm while the latter study used 550 versus 1000 ppm. Whether the increase in the risk of fluorosis in the former study was due to the higher fluoride level of the toothpaste was confounded by the longer duration of exposure and the younger age at which use of fluoride toothpaste was started. In addition, results from the meta-analysis in pooling the data from the cross-sectional surveys did not support the association between the fluoride concentration of toothpaste used and fluorosis. However, it is noted that the pooled OR (0.79) was only marginally insignificant (random-effects (RE): 95% confidence interval (CI) 0.61 to 1.02; P = 0.07). More evidence with low risk of bias is needed to clarify the inconsistency in the association.

It was originally intended to analyse the associations with respect to the different exposure of systemic fluoride using subgroup analysis, however, with very few studies being available for such comparison, subgroup analysis was not performed. Only information on the number of studies conducted in fluoridated, non-fluoridated or both fluoridated and non-fluoridated areas was reported in each comparison.

The available evidence shows an increased association of fluorosis and age started using fluoride toothpaste/toothbrushing before 12 months, and an inconsistent association between fluorosis and age started using fluoride toothpaste/toothbrushing before 24 months. From the RCTs, higher concentration of fluoride toothpaste was associated with an increase in fluorosis, even though such find-
ing is not supported by the data from cross-sectional surveys. No significant association between the frequency of toothbrushing or the amount of fluoride toothpaste used and fluorosis was found.

**Authors’ Conclusions**

**Implications for practice**

There should be a balanced consideration between the benefits of topical fluorides in caries prevention and the risk of the development of fluorosis. Most of the available evidence focuses on mild fluorosis. There is weak unreliable evidence that starting the use of fluoride toothpaste in children under 12 months of age may be associated with an increased risk of fluorosis. The evidence for its use between the age of 12 and 24 months is equivocal. If the risk of fluorosis is of concern, the fluoride level of toothpaste for young children is recommended to be lower than 1000 ppm.

**Implications for research**

More evidence with low risk of bias is needed. Future trials assessing the effectiveness of different types of topical fluorides (including toothpastes, gels, varnishes and mouthrinses) and/or different concentrations should ensure that they include an adequate follow-up period in order to collect data on potential fluorosis. As it is unethical to propose randomised controlled trials to assess fluorosis itself, it is acknowledged that further observational studies will be undertaken in this area. However, attention needs to be given to the choice of study design, bearing in mind that prospective, controlled studies will be less susceptible to bias than retrospective and/or uncontrolled studies.

**Acknowledgements**

Thanks go to Sylvia Bickley and Anne Littlewood (Trials Search Co-ordinator, Cochrane Oral Health Group) for carrying out the searches for the review; Philip Riley (Assistant Managing Editor, Cochrane Oral Health Group) for his help with the administration of the review which included locating all the articles for the review. Thanks also to Luisa Fernandez Mauleffinch (Managing Editor, Cochrane Oral Health Group) for her help with the administration of the review. Our thanks also to those who assisted with translation of the foreign language manuscripts. We would also like to thank the referees for all their constructive comments.

### Pereira 2000

**Methods**  
Cross-sectional survey conducted in a non-fluoridated city in Brazil

**Participants**  
Children 11-12 years old randomly selected from school lists and 314 gave parental consent and were examined and parental questionnaires

**Interventions**  
Exposure: age started using fluoride toothpaste.

**Outcomes**  
TFI.

**Notes**  
Intra-examiner reliability (Kappa >0.85).

### Riordan 1993

**Methods**  
Cross-sectional survey conducted in a fluoridated area in Western Australia

**Participants**  
418 invited to participate and 350 children 7 years old examined and with parental questionnaires

**Interventions**  
Exposure: age started using fluoride toothpaste.

**Outcomes**  
TFI.

**Notes**  
Intra-examiner reliability (weighted Kappa = 0.78).

### Riordan 2002

**Methods**  
Cross-sectional survey conducted in fluoridated and non-fluoridated areas in Western Australia

**Participants**  
Randomly selected 14 schools in fluoridated area and 1 school in non-fluoridated area. 672 were invited and 582 10 years old children remained and with parental questionnaires

**Interventions**  
Exposure: age started using fluoride toothpaste.

**Outcomes**  
TFI.

**Notes**  
Intra-examiner reliability (weighted Kappa = 0.75).

### Rock 1997

**Methods**  
Cross-sectional survey conducted in a fluoridated area in UK

**Participants**  
326 invited and 325 8-9 years old children from 5 junior schools were examined with parental questionnaires

**Interventions**  
Exposure: frequency of toothbrushing, age started toothbrushing, type of fluoride toothpaste, amount of fluoride toothpaste used at the time when toothbrushing with fluoride toothpaste started

**Outcomes**  
TFI.
### Rock 1997 (Continued)

**Notes**

Intra-examiner reliability (Kappa value not reported).

<td>Fluorosis in relation to total fluoride intake was investigated, no data on the effects of topical fluoride could be separated for analysis</td>
</tr>
<tr>
<td>Houwink 1979</td>
<td>Controlled clinical trial investigating enamel defects not specifically for fluorosis</td>
</tr>
<tr>
<td>Kumar 2000</td>
<td>The analysis of the effect of early brushing has been investigated in different combinations with the effects of water fluoridation and fluoride supplement, no data on the effect of early brushing could be separated for analysis</td>
</tr>
<tr>
<td>Larsen 1985a</td>
<td>Retrospective cohort investigating the effects of fluoride gel treatment started at 6-7 years of age</td>
</tr>
<tr>
<td>Larsen 1985b</td>
<td>Retrospective cohort. Fluoride tablets plus toothbrushing at school with fluoride toothpaste compared with nothing. No comparison of TFT versus other TFT, placebo or nothing</td>
</tr>
</tbody>
</table>
Levy 1991 | Fluorosis was not clinically assessed.
---|---
Machado 2008 | Study report unobtainable.
Martignon 2000 | Conference abstract, insufficient information reported.
Martins 2008 | Cohort study. 2 convenience samples based on socioeconomic status rather than fluoride exposure. Data not usable
Momeni 2007 | No differentiation between different fluoride preventive programmes
Nowjack-Raymer 1995 | Database no longer exists - data from 5 years old cannot be extracted
Toassi 2005 | Uncertain of timing of exposure to topical fluoride.
van der Hoek 2003 | DDE Index was used to assess diffuse opacities as an approximation to fluorosis
Wetzel 1989 | Case series or single cohort study, unclear investigation of topical fluoride exposure before the age of 6 years
Wotlgens 1989 | Children in one group all took fluoride tablets, no investigation of the exposure of topical fluoride

DDE Index = Developmental Defects of Enamel Index; TFT = topical fluoride therapy.

</tr>
<tr>
<td>Morgan 1998</td>
<td>The fluoride history variables, in aggregate, were not significantly associated with clinical assessments of fluorosis</td>
<td>No estimates of ORs or count data were reported.</td>
</tr>
<tr>
<td>Pendrys 1989</td>
<td>Mantel-Haenszel OR estimates, adjusted for fluoride supplement, showed no statistically significant association between the use of fluoride dentifrice throughout the third through sixth years of life and fluorosis on any enamel surface (OR = 2.9, 99% CI 0.5 to 15.8)</td>
<td>Fluorosis Risk Index was used.</td>
</tr>
<tr>
<td>Pendrys 1994</td>
<td>Frequent brushing with fluoride toothpaste throughout the first 8 years conveyed an increase in the risk of fluorosis on FRI classification I (OR = 2.80, 95% CI 1.15 to 6.81) and classification II (OR = 2.63, 95% CI 1.03 to 6.73) enamel surfaces as compared with non-frequent brushing. The reported usual use of more than a pea size amount of toothpaste during brushing was not found to be statistically significant (classification I: OR = 3.07, 95% CI 0.76 to 12.36; classification II: OR = 1.75, 95% CI 0.35 to 8.89)</td>
<td>Fluorosis Risk Index was used.</td>
</tr>
<tr>
<td>Pendrys 1996</td>
<td>A history of beginning to brush during the first 2 years while usually brushing more than once per day with fluoride toothpaste conveyed statistically significant adjusted ORs of 2.56 (95% CI 1.34 to 4.88) and 4.23 (95% CI 1.72 to 10.41) for mild-to-moderate fluorosis on FRI classification I and II enamel surfaces, respectively, as compared with subjects who did not begin to brush until after the second year and who usually brushed only once per day</td>
<td>Fluorosis Risk Index was used.</td>
</tr>
<tr>
<td>Pendrys 1998</td>
<td>A history of usually brushing with more than a pea size amount of toothpaste with a frequency of more than once per day conveyed statistically significant adjusted ORs of 6.35 (95% CI 1.21 to 33.40) and 8.37 (95% CI 1.68 to 41.72) for mild-to-moderate fluorosis on FRI classification I and II enamel surfaces, respectively, as compared with subjects who usually used a pea size amount of toothpaste and brushed only once per day</td>
<td>Fluorosis Risk Index was used.</td>
</tr>
<tr>
<td>Pereira 2002</td>
<td>Children who started using fluoride toothpaste before the age of 3 were 4.43 times more likely to have dental fluorosis than those who started using it after the age of 3</td>
<td>TF&gt;1 was used as criterion for defining fluorosis instead of TF&gt;0 used in the review</td>
</tr>

Osuji 1998
- Is the case definition adequate? Yes: Comment: TFI > 0 and intra-examiner reliability assessed.
- Representativeness of the cases? Yes: Comment: Invited all schools >100 children.
- Selection of controls? Yes: Comment: Examined all children from the same classes with age and sex matched.
- Definition of controls? Yes: Comment: TF score = 0.
- Comparability of cases and controls? Yes: Comment: Children in the same classes and age and sex matched.
- Ascertainment of exposure? Yes: Comment: Interviewer not blinded, however time gap between screening and interview. No blinding for the parents, not possible to blind the parents.
- Same method of ascertainment of cases and controls? Yes
- Adequate response rate? Yes: Comment: 82% for cases and 84% for controls.

Pendrys 1989
- Is the case definition adequate? Yes: Comment: Fluorosis positive score on 2 or more enamel surface zones assigned to 1 of the 2 classifications (according to age of formation) in the Fluorosis Risk Index.
- Representativeness of the cases? Unclear: Comment: 1242 fluorosis examinations undertaken of 11 to 14 year olds. Unclear if all schools in area included. 850 cases and controls of the 1242 ‘selected’.
- Selection of controls? Yes: Comment: Children from same population, sex and age matched to within 6 months.
- Definition of controls? Yes: Comment: No fluorosis positive or questionable scores on any of the surface zones assigned to each classification in the Fluorosis Risk Index.
- Comparability of cases and controls? Yes: Comment: Children age and sex matched.

HISTORY

Protocol first published: Issue 2, 2009

Review first published: Issue 1, 2010
CONTRIBUTIONS OF AUTHORS

Designing the review: May Wong (MW), Edward Lo (EL), Helen Worthington (HW)
Co-ordinating the review: Valeria Marinho (VM), Anne-Marie Glenny (AMG), Boyd Tsang (BT)
Undertaking searches and screening search results and retrieved papers against inclusion criteria: MW, EL, BT
Appraising quality and extracting data from papers: HW, AMG, MW, VM
Writing to authors for additional information: EL, MW
Data management for the review and entering data into RevMan: MW
Analysis and interpretation of data: HW, MW, VM
Writing the review: MW, EL, HW, VM, AMG, BT
Providing general advice on the review: EL, HW, VM.

DECLARATIONS OF INTEREST

Helen Worthington has an office located in the University of Manchester's Dental Health Unit which is jointly supported by the University of Manchester and Colgate Palmolive. Helen Worthington does not receive any funding from Colgate Palmolive and does not view this as a conflict of interest. There are no other known potential conflicts of interest.

SOURCES OF SUPPORT

Internal sources

• School of Dentistry, The University of Manchester, UK.
The University of Manchester pays the salaries of Helen Worthington and Anne-Marie Glenny. The Cochrane Oral Health Group is supported by the Department of Health, the Manchester Academic Health Sciences Centre (MAHSC) and the NIHR Manchester Biomedical Research Centre.

• The University of Hong Kong, CRCG grant, Hong Kong.

External sources

• Department of Health Cochrane Review Incentive Scheme 2008, UK.
Provided GBP 5000 to support this review.
• National Institute for Health Research (NIHR), UK.
Funds the editorial base of the Cochrane Oral Health Group.
